

Boosting System for Fuel Cell vehicles

Galen Korosec, Gigi Wong, Ryan Jessop, Shreyan Mandal & Yaoquan Tang

March 25, 2022

Abstract

The report details the initial development stage of a hydrogen fuel cell testing rig. A hydrogen fuel cell is a type of power cell capable of converting the chemical energy of hydrogen into electricity. Its method of operation utilises hydrogen and air/oxygen particles and the testing rig is planned to be utilised to test how a hydrogen fuel cell performs for efficiency when provided with varying pressure ratios of the incoming gases. It is proposed that the development of the testing rig will involve numerous subsystems of the testing rig which are air intake and boosting, heat management systems, water management systems and system regulation of gas characteristics. It is noted that interest in fuel cell performance has grown due to the recent political pushes toward greater development of more environmentally conscious methods of transport.

1 Introduction

Fuel cell vehicles are gaining increased attention for authorities and industries to align with the Carbon Net-Zero target by 2050. To achieve the goal of limiting global temperatures rise to 1.5 °C, global demand for hydrogen fuel is expected to sixfold to 530 million tonnes in 2050; By then, 90% of road transport should be powered by renewable energy, with 37% being hydrogen-fuelled vehicles [1]. The Hydrogen Roadmap Europe has projected that there will be 3.7 million fuel cell vehicles on the road by 2030 [2], implying that the figure in 2050 could go as high as 9.8 million vehicles.

Despite the rigorous forecast in demand for hydrogen-fuelled vehicles, there are various difficulties in promoting this technology, mainly due to the low power converting efficiency [3]. This project intends to increase power efficiency and explore the feasibility of developing a boosting system for hydrogen Fuel Cell Vehicles (FCV). A test rig is also designed to measure the booster efficiency.

This report first addresses the primary and secondary objectives of the project; second, it explains the background of the selection of system components, including the type of fuel cell and forms of hydrogen; finally, it goes into the overview of the proposed solution, which comprehends by the complete picture of the entire system and the five supporting subsystems.

2 Objectives

The subject is researching the booster system that increases the efficiency of the FCVs. As mentioned, a test rig will be designed. Data will be collected in the test rig, which will be used for quantifying measurement and simulation to prove feasibility. This should contain a variety of sensors responsible for measuring temperature, pressure, humidity, flow, etc. The data collected will be input into the designed system console for analysis. At the same time, appropriate electronic load devices will be used, which will be responsible for measuring the output power of the fuel cell.

According J.Hoeflinger[4], the higher the reaction pressure, the higher the fuel cell's performance. Therefore, the control variable method is adopted. First, experiments are carried out with hydrogen under constant pressure, and the power of the battery system is tested by controlling the pressure of the air in which the reaction is carried out. Then, experiments are carried out with air under constant pressure, and the power of the battery system is tested by controlling the pressure of hydrogen gas. At the same time, factors such as temperature and humidity that may affect the experimental results should also be considered. Finally, the project will identify the maximum power generation efficiency that can be safely achieved under experimental conditions.

3 Background

In 2019 27% of UK emissions came from road transport [5]. To reach the UK's and global emissions targets, alternatives to the internal combustion engine need to be considered. Fuel cell electric vehicles (FCEVs) provide an attractive option [6]. A fuel cell vehicle uses hydrogen as its fuel source. Electricity is generated via a chemical reaction between oxygen and hydrogen to create water; as can be seen in equation 1. This electricity is stored in a battery and uses an electric motor to move. One of the main advantages of an FCEV over a traditional battery-powered electric vehicle (BEV) is the refuelling time. A typical electric car such as the Nissan LEAF takes 7 hours 30 minutes to fully recharge from empty, giving a range of 168 miles [7]. Compared to the 3 minutes of an FCEV like the Toyota Mirai [6].

While the exact reaction differs between fuel cell types, the general process can be seen in diagram1 [8]. The system is composed of an anode, a cathode, an electrolyte and the load or external circuit. At the anode, hydrogen is oxidised into protons and electrons. At the cathode, oxygen is ionised, then depending on the electrolyte type, either the oxygen ions or the protons are transported over the electrolyte. At the same time, the electrons travel externally to provide electrical power [8].

Figure 1: Diagram of the general operating principles of a fuel cell [8]

Currently, there are three main types of fuel cells used in road vehicles, Polymer Electrolyte Membrane (PEM), Alkaline fuel cells (AFCs), and Phosphoric Acid fuel cells. A summary of each can be seen in table 1. PEM is used most in FCEVs. Its high usage is due to its low operating temperatures, quick start-up time and ability to use atmospheric air[9]. However, it uses Platinum as a catalyst which increases its cost. AFCs operate similarly to PEMs. However, they use an alkaline electrolyte instead of an acid-based one used in the PEMs. The AFC electrolyte transports OH⁻ ions from the cathode to the anode. Finally, there is Phosphoric acid fuel cells they have the potential to be incredibly efficient with results as high as 80-85% when reclaiming the heat[3]; however without this additional system it is around 40%. For these reasons the test rig was designed around the PEM.

Common fuel cell comparison				
Fuel Cell	Operating temperature	Catalyst type	Operating pressure	Electrical efficiency
PEM	50-100°C	Platinum	3-4 bar	50-60%
AFC	90-100°C	Nickle/Silver	3-4 bar	60-70%
Phosphoric Acid	150-200°C	Platinum	7507	80-85%(with combined heat and power) 40% electric

Table 1: Table comparing different fuel cells[3][9]

To improve the attractiveness of fuel cell vehicles, their efficiency needs to be improved. For PEM fuel cells, research has shown that controlling the incoming air pressure can increase the system efficiency [4]. As the fuel cell technology improves, the boosting needs to be optimised; for this reason, a testing rig to assist with the investigation into the effects of boosting is beneficial.

4 Overview of Proposed solution

As stated by Pukrushpan [10] and other researchers, a typical fuel cell system usually includes the system's reactant flow, heat and temperature, water management and power management.

However, this conventional partitioning is not fully applicable to incorporate a booster. Therefore, the fuel cell boosting system is re-partitioned to segregate the air intake and boosting system as an individual module, with the heat, water and power management as supporting modules. In addition, a regulatory module is introduced to have parameters within the system adjusted or consistent in a controlled manner.

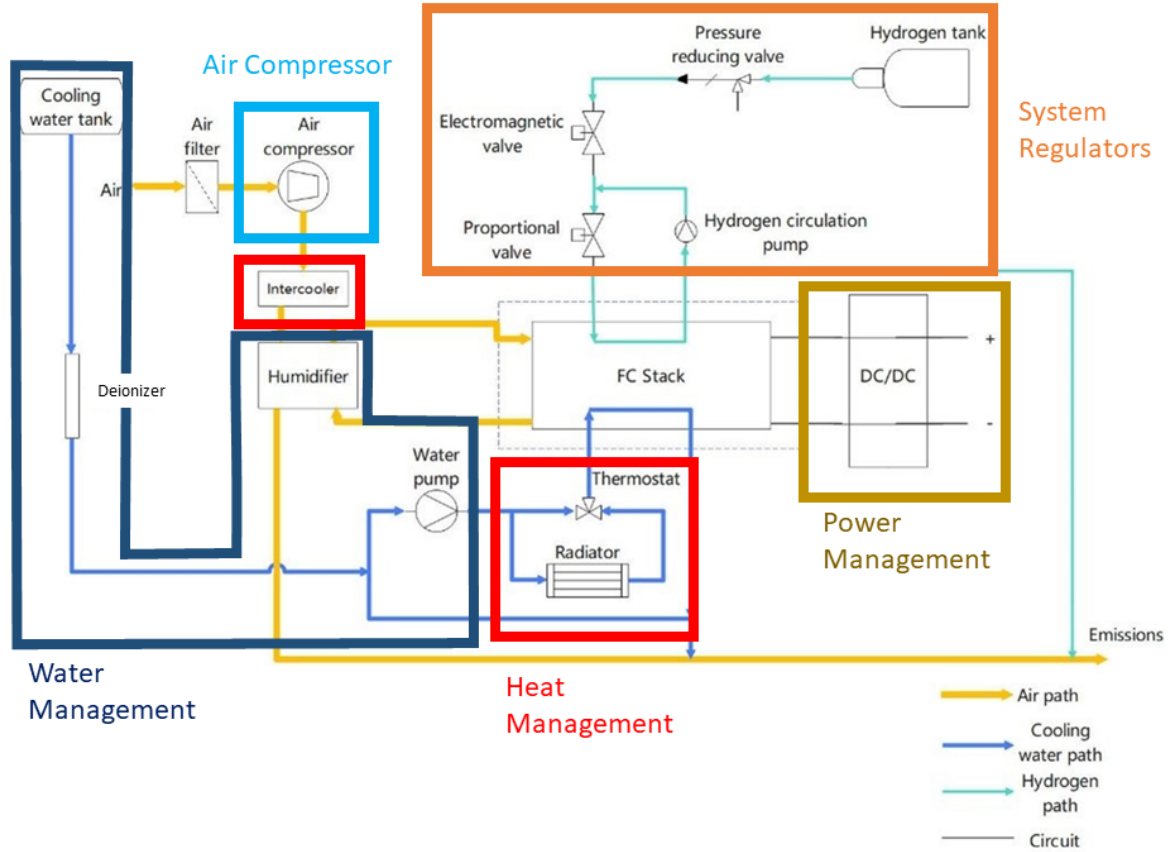

Figure 2: Diagram of the proposed boosting systems

Figure 2 illustrates the flow of the reactants and their interaction with each subsystem. The diagram also indicates the intercorrelation between the subsystems and how they integrate to form the complete boosting system.

4.1 Air Intake and Boosting

The air intake and boosting system will be the initial point where the ambient air at atmospheric pressure enters the system. The project brief aims to develop a testing rig for the fuel cell's power output at varying pressure ratios. This suggests that the boosting system needs to take the ambient air at atmospheric pressure and supply the system with the relevant ratios. The first stage in the project will be to determine a definitive range of pressure ratios that must be provided to the fuel cell to carry out the appropriate testing. This can be done by reading relevant literature on alternate methods of fuel cell tests on comparable fuel cell stack sizes and how the cells performed for these pressure ratios. For example, the study on the optimal pressure ratios of a PEM fuel cell[4] indicated that the tested pressure ratios were between 1.0 and 2.2. A further review of multiple studies into the relevant fuel cells will show the necessary ratios.

In terms of designing the boosting system to provide a variable pressure ratio, the stages described in figure 3 are planned to regulate the values of pressure and the flow speed entering the concurrent subsystems. The ambient air temperature will also impact these values and the work

required of the compressor. The Steady Flow Energy equation(2), can be utilised to determine the values from the compressor to the intake receiver when consulting the operating power of the compressor's impeller[11]. Here the values of \dot{Q} represents the rate of heat added to the system to \dot{W}_{ext} , the rate of work done. The values for \dot{m} , mass flow rate of air in the compressor which as the steady flow implies remains constant, h_n , enthalpy entering or leaving the system, V_n , speed of the air and z_n , the height at which the air enters or leaves the system, will be explored in the following works to describe how they can be found (note that g describes acceleration due to gravity). This will the bassline amount power needed to operate the compressor, which will then need more to account for losses. Note that mass air flow valves and pressure gauges will be utilised in the subsystem to provide these necessary values.

$$\dot{Q} - \dot{W}_{ext} = \dot{m}((h_2 + \frac{1}{2}V_2^2 + gz_2) - (h_1 + \frac{1}{2}V_1^2 + gz_1)) \quad (2)$$

The option to examine the effect of directly injecting oxygen into this system will be implemented. Here, the studies into relevant literature can also provide input on the impact of different levels of oxygen percentages entering the fuel cell. As part of investigating this option, the values of oxygen percentages in the incoming air will need to be kept track of. Further, the input location of such oxygen will need to be determined in conjunction with the other systems.

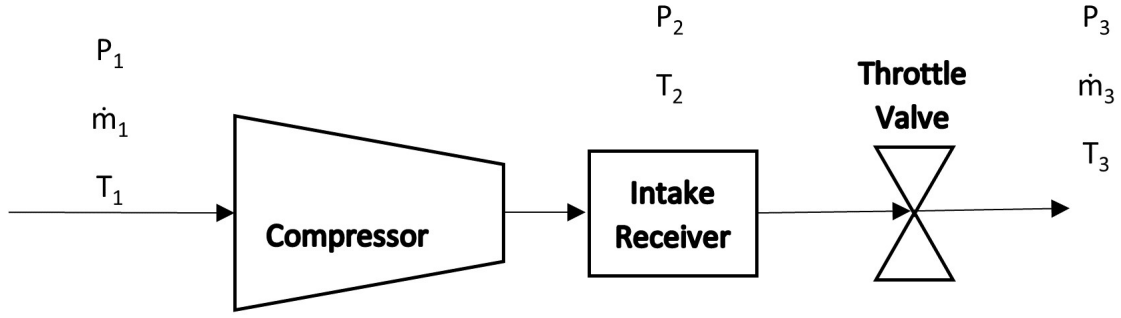

Figure 3: Diagram of the air intake system

4.2 Heat Management

Other subsystems are also vital in supporting the entire boosting system and the compressor. Heat Management is essential to maintain the system thermal and energy stability to withstand different environmental conditions. Steady-state operation of the fuel cell stack is critical to ensure maximum power output efficiency.

The heat exchange mechanism of fuel cells involves two parts, heating and cooling. The PEM fuel cell needs to be maintained at thermal equilibrium at 50-100°C throughout the operation for maximum efficiency. The hydrogen and oxygen need to be heated to the same temperature when entering the fuel cell stack. On the other hand, a cooling system is necessary to remove extra heat generated during the fuel cell reaction. Four cooling strategies are commonly used in fuel cell vehicles (as shown in Table 2). For a typical FCEV with 100kW power, edge cooling or heat spreader is insufficient; air flow cooling cannot be made efficient either without reducing the fuel cell reaction rate[12]. Phase change cooling is generally desirable but external coolant is required for vaporization cooling. Thus liquid cooling is most widely adopted on high power FCS for its strong cooling capability[13]. In this design, liquid cooling is selected as it allows recovering up to 36% of energy from waste heat (Figure 4) by combining with output water as

coolant. This approach increases the system's overall power efficiency from recovering excess heat energy and up-cycles the water output as a coolant and humidifier for the gases.

Cooling Strategy	Advantages	Limitations
Edge Cooling[14]	Simple setup, small parasitic power	Low efficiency
Separate Air Flow[15]	Simple setup, small parasitic power	A trade-off between efficiency and parasitic power
Liquid Cooling[13]	Strong cooling power	Large radiator
Phase Change Cooling[16]	Strong cooling power, no coolant pumps	Complex setup, instability

Table 2: Cooling Strategies in FCEV[17]

Figure 4: Shankey Diagram showing hydrogen energy flow in a PEMFC[13]

The biggest challenge to the liquid cooling system in PEM is the insignificant difference in temperature between the fuel cell (50-100°C) and the ambient temperature (average 25°C) compared to most of the ICEs[18]. This implies a large size radiator would be required for effective cooling, which is however undesirable in designing a light-weighted, compact vehicle. Another challenge arises from collaboration with other subsystems. Various parameters, include gases temperature at compressor outlet and water volume produced in FCS (Table 3), are critical in designing an efficient and precise heat exchange system.

Subsystem	Parameters required	Dependency in HMS
Air Compressor	Gases temperature at the outlet	Inputs of heat exchanger
Water Management	The volume of water output in FCS	The volume of coolant required
H2 Pressure regulator	Gases temperature at the outlet	Inputs of heat exchanger
	Parameters provided	Dependency in subsystem
Power Management	The power needed for the heat exchanger	Total power required

Table 3: Dependencies of HMS and other subsystems[10]

Further analysis on the proposed thermal equilibrium by waste heat recovering liquid cooling system will be carried on, where the detailed methodology will be presented in the individual technical report.

4.3 Water management systems

The heat dissipation of hydrogen fuel cell vehicles has always been a significant difficulty. There are many reasons for heat generation, including chemical heat generated by the reaction, heat brought into the system by the humidified gas, etc. To ensure that the fuel cells can work optimally, there must be adequate cooling throughout the whole system. So, this project proposes a thermal management system. In thermal management systems, the use of coolant is one of the most efficient methods of dissipating heat. In Figure 5, the cooling water paths are highlighted in different colours. According to the layout, the water management system can be divided into two parts, coolant and generated water.

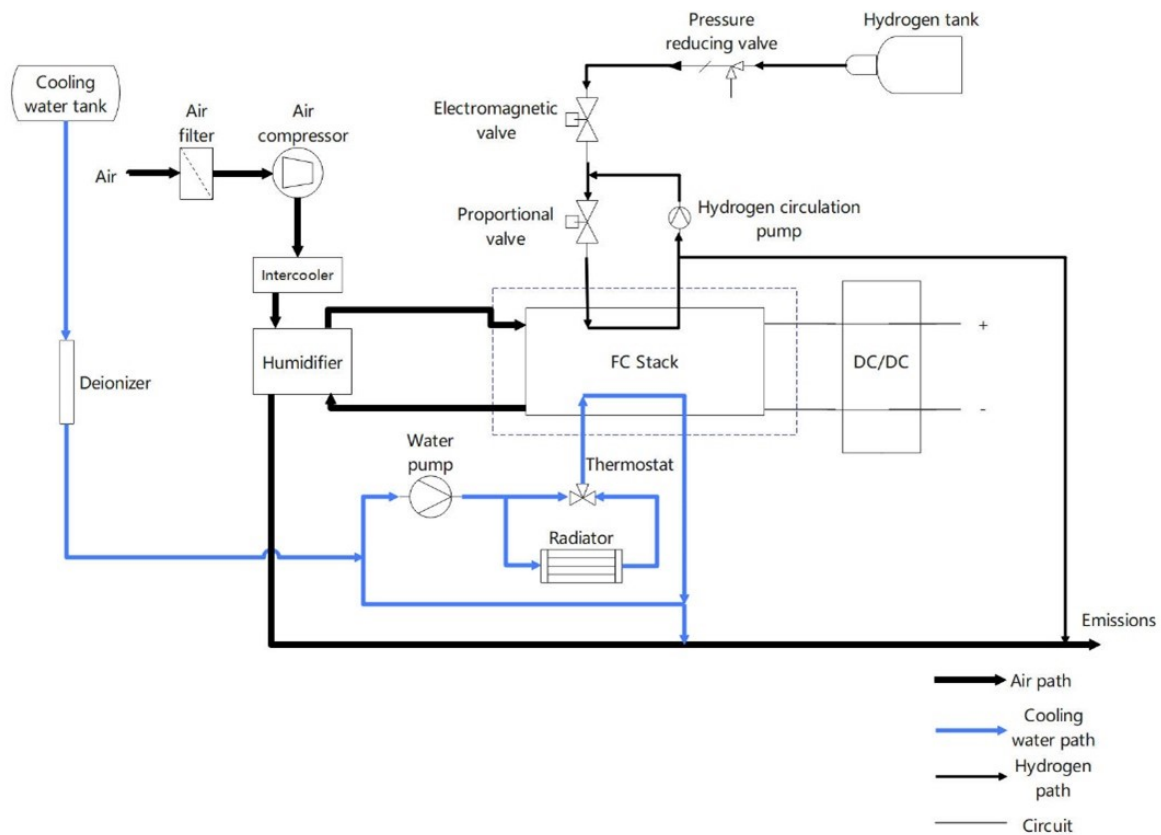

Figure 5: Diagram of the path of the cooling water

On one hand, during the operation of the hydrogen fuel cell, the ionic content of the coolant will increase, which will lead to an increase in its electrical conductivity and a decrease in the system insulation[19]. Therefore, deionisers are proposed to improve this phenomenon. By absorbing the anions and cations released from components, it ensures that the system is always at a high level of insulation. In addition, the thermostat in the layout can automatically adjust the amount of liquid participating in the heat dissipation of the battery according to the temperature of the cooling liquid to ensure that the fuel cell works within a suitable temperature range, which can save energy consumption.

On the other hand, inside the reactor, water is produced as hydrogen reacts with oxygen. The production of this part of the water takes away a lot of heat. The water can be recycled to a certain extent, which means the radiator can cool it, then repeatedly lower reactor temper-

ature. The water management system can efficiently cool the entire battery system and is an indispensable part of hydrogen fuel cell vehicles.

4.4 System regulation

Specific parameters need to be controlled throughout the system for the fuel cell. For example, for the hydrogen, the pressure from the storage tank will initially be extremely high, and the moment it enters the fuel cell, it would have to decrease to a lower pressure, i.e. 4 bar [4].

Other than pressure, the overall temperature will also need to be maintained. As previously mentioned, the operating temperature range for the fuel cell is between 50° to 100°. If the overall temperature is beyond its operating temperature, it could further damage the fuel cell and lower efficiency in producing electricity[20].

Finally, filters will be required. The oxygen used for the fuel cell will come from the ambient air. Ambient air will not only contain oxygen; it also consists of other gases such as Nitrogen and Sulfur Dioxide[21]. If they are within the system, it could cause corrosion in the fuel cell. Thus, it is essential to have the 'contaminants' filtered out before going to the fuel cell.

4.5 Power management

To power, all these subsystems' ample energy needs to be provided. As it is a test rig, it will be supplied using mains power supplies; however, to investigate if the compressor is beneficial, the system must be able to emulate the realities of using these elements in a vehicle. Therefore, the system must ensure that the additional power provided by the compressor is greater than the power it consumes.

4.6 Test rig

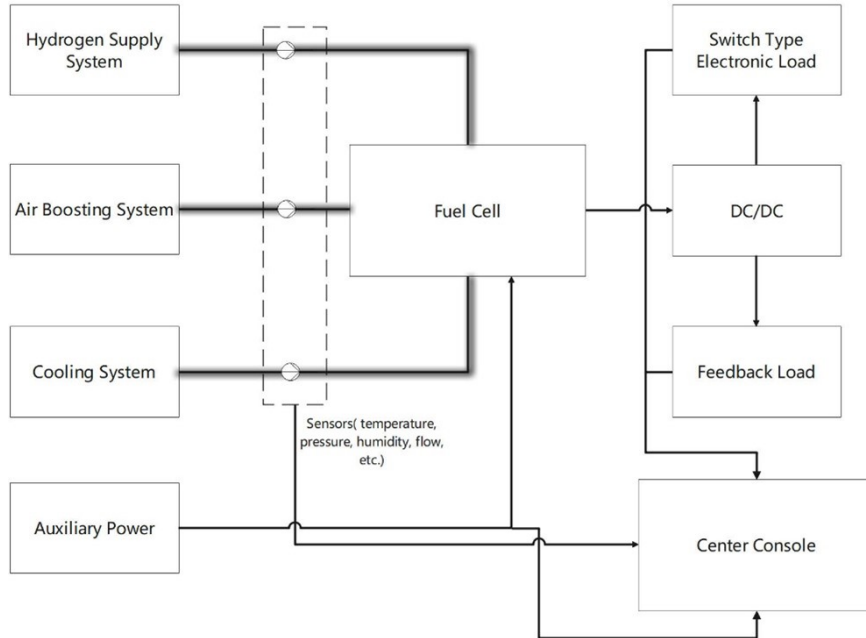

Figure 6: The layout of the test rig

The primary purpose of the test rig is to analyse the collected data to support the project's conclusions. First, the test rig should contain devices for data acquisition, such as various

sensors. Secondly, the test rig should also provide an electronic load device to measure the output power of the fuel cells. At the same time, to prevent the power from being too large and a large amount of energy output during the load, which affects the stability of the test system, the test rig should use a feedback load. It can use the power electronic conversion technology to recycle the output energy of the tested power supply under the premise of completing the test power experiment and feeding the electric energy back to the power grid without pollution, avoiding the problem of the environmental temperature increase in the test site. Finally, the test system should also have a centre console that can integrate all the collected data for analysis and ultimately provide the basis for project conclusions. Overall, the test rig layout for the project design is shown in figure 6.

5 Group Organisation

Initially, the group has decided to rotate the project manager and secretary roles each week. After the presentation, the decision was made to select one member to focus on each position as it was found that it was not easy to keep a clear objective and hold each other accountable. The project manager is Gigi Wong, and the secretary is Galen Korosec. Each group member is responsible for a subsystem; the individual assignments can be seen in the table below

Subsystem	Group member
Compressor & Boosting system	Ryan Jessop
Heat Management	Gigi Wong
Water Management	Yaoquan Tang
System Regulation	Shreyan Mandal
Power Management	Galen Korosec

Table 4: subsystems allocation

To ensure the schedule, which can be seen in appendix A, was able to be followed, meetings were scheduled for every Monday and Wednesday. These meetings were used to discuss the progress made on the tasks assigned in the previous week, any questions or issues that needed to be addressed, and set the tasks for the following week.

6 Conclusion

With the expected rapid growth in demand for clean fuelled transport, fuel cell vehicles are undoubtedly the future of the automobile. However, the most common type of hydrogen fuel cell, PEM, currently encounters a significantly low power converting ratio deficiency. This project introduces a potential solution of a boosting system to increase the efficiency of hydrogen FCEV. The overall system design comprises five correlated subsystems, namely the air compressor, heat management system, water management system, regulatory system, and power management system. The plan also incorporates a testing rig to quantify the system efficiency. Based on the system architecture proposed in this report, the group will continue to work on the detailed design of each subsystem. The final design will be justified based on the system's overall efficiency, cost and power, which will be unfolded in the final technical report.
